MOLECULAR INTERACTIONS: WHEN BIOSENSORS COUNT

Giovanni Nava

Dipartimento Biometra, Università degli Studi di Milano

The detection of molecules or viruses in low concentrations regimes is a critical requirement in the field of diagnostics and biomedical research. Such challenge is the goal of the so called “digital” technologies applied to biosensors which is now, after the insurgence of SARS-CoV-2, of key interest for point-of-care and clinical diagnostic applications. Analogously to digital-PCR, the goal of digital biosensors is to “count” the single events of interaction between a molecule (or a virus) and a specific receptor, e.g. antibodies, immobilized on a surface. In order to achieve such result, digital detection schemes rely on amplification methods (optical, electrical, chemical) to transduce the single binding event in a single measurable signal, which in time becomes a counting signal. We developed a digital version of Reflecting Phantom Interface -a label-free biosensor technology born in BIOMETRA- that enables detecting single binding events in the femtomolar concentration regime. The “digital” label-free optical biosensor relies on a simple detection scheme based on a LED source and a functionalized surface where the receptors are spotted. The first results obtained with virus analogues and viral nucleic acids will be presented.
